MARKOV CHAIN MONTE CARLO SIMULATION METHODS IN ECONOMETRICS

SIDDHARTHA CHIB AND EDWARD GREENBERG
Washington University

We present several Markov chain Monte Carlo simulation methods that have been widely used in recent years in econometrics and statistics. Among these is the Gibbs sampler, which has been of particular interest to econometricians. Although the paper summarizes some of the relevant theoretical literature, its emphasis is on the presentation and explanation of applications to important models that are studied in econometrics. We include a discussion of some implementation issues, the use of the methods in connection with the EM algorithm, and how the methods can be helpful in model specification questions. Many of the applications of these methods are of particular interest to Bayesians, but we also point out ways in which frequentist statisticians may find the techniques useful.

1. INTRODUCTION

In this paper we explain Markov chain Monte Carlo (MCMC) methods in some detail and illustrate their application to problems in econometrics. These procedures, which enable the simulation of a large set of multivariate density functions, have greatly expanded the domain of Bayesian statistics and appear to be applicable to many complex parametric econometric models. Our purpose is to explain how these methods work both in theory and in practical applications. Because many problems in Bayesian statistics (such as the computation of posterior moments and marginal density functions) can be solved by simulating the posterior distribution, we emphasize Bayesian applications, but these tools are also valuable in frequentist inference, where they can be used to explore the likelihood surface and to find modal estimates or maximum likelihood estimates with diffuse priors.1

An MCMC method is a simulation technique that generates a sample (multiple observations) from the target distribution in the following way: The transition kernel of a Markov process is specified with the property that its...
limiting invariant distribution is the target distribution. The Markov chain is then iterated a large number of times in a computer-generated Monte Carlo simulation, and the output, after a transient phase and under various sets of conditions, is a sample from the target distribution. The first such method, by Metropolis, Rosenbluth, Rosenbluth, Teller, and Teller (1953) and Hastings (1970), is known as the Metropolis–Hastings (MH) algorithm. In this algorithm, the next value of the Markov chain is generated from a proposal density and then accepted or rejected according to the target density at the candidate point relative to the density at the current point. A special case of the MH method is the Gibbs sampling algorithm, introduced by Geman and Geman (1984) and extended by Tanner and Wong (1987) and Gelfand and Smith (1990), in which the next draw is obtained by sampling subcomponents of a random vector from a sequence of full conditional distributions. Other MCMC methods include hybrid MH and rejection sampling (Tierney, 1994) and stochastic versions of the EM algorithm (Celeux and Diebolt, 1985).

The generated sample can be used to summarize the target density by graphical means, by exploratory data analysis methods, and by other means. For example, expectations of integrable functions w.r.t. the target density can be estimated by taking a sample average of the function over the simulated draws. Under general conditions, the ergodicity of the Markov chain guarantees that this estimate is simulation-consistent and satisfies a central limit theorem as the length of the simulation goes to infinity. The MCMC strategy has proved extremely useful in statistical applications, much more so than traditional independent sampling methods, which by and large are difficult to apply in complex, high-dimensional problems. MCMC methods can be applied without knowledge of the normalizing constant of the target density, which is very important in the Bayesian context where the normalizing constant of the target (posterior) density is almost never known. In addition, it is often possible to tailor an MCMC scheme so that models with an intractable likelihood function can be simulated. This is usually achieved, particularly with Gibbs sampling, by the device of “data augmentation” (the strategy of enlarging the parameter space to include missing data or latent variables). Applications of this idea include models with structural breaks at random points (Carlin, Gelfand, and Smith, 1992), models with censored and discrete data (Chib, 1992b; Albert and Chib, 1993a), models with Markov switching (Albert and Chib, 1993b; Chib, 1993a; McCulloch and Tsay, 1994), models with parameter constraints (Gelfand, Smith, and Lee, 1992), and many others.

The remainder of the paper proceeds as follows. In Section 2, we review the theory behind generating samples by MCMC methods and discuss implementation issues for the Gibbs and MH algorithms. In Section 3, these methods are applied to models widely used in econometrics: the seemingly unrelated regression model, the Tobit censored regression model, binary probit models, state-space models, and linear regression with AR(p) errors.
In Section 4, we explain how output from an MCMC simulation can be used for statistical inference, and Section 5 contains conclusions.

2. MCMC SAMPLING METHODS

We begin the section with an informal presentation of some relevant material from Markov chain theory and then discuss the Gibbs sampling algorithm and the MH algorithm. A much more detailed discussion of Markov theory is provided by Nummelin (1984), Meyn and Tweedie (1993), and Tierney (1994).

2.1. Markov Chains

A Markov chain is a collection of random variables (or vectors) \( \Phi = \{ \Phi_i : i \in T \} \), where \( T = \{0, 1, 2, \ldots \} \). The evolution of the Markov chain on a space \( \Omega \subseteq \mathbb{R}^d \) is governed by the transition kernel

\[
P(x, A) = \Pr(\Phi_{i+1} \in A | \Phi_j = x, \Phi_j, j < i)
\]

\[
= \Pr(\Phi_{i+1} \in A | \Phi_i = x), \quad x \in \Omega, A \subseteq \Omega.
\]

The assumption that the probability distribution of the next item in the sequence, given the current and the past states, depends only on the current state is the Markov property. Let the transition kernel, for some function \( p(x, y) : \Omega \times \Omega \to \mathbb{R}^+ \), be expressed as

\[
P(x, dy) = p(x, y)v(dy) + r(x)\delta_x(dy),
\]

where \( p(x, x) = 0, \delta_x(dy) = 1 \) if \( x \in dy \) and 0 otherwise, \( r(x) = 1 - \int_\Omega p(x, y)v(dy) \), and \( v \) denotes a \( \sigma \)-finite measure on the Borel \( \sigma \)-algebra on \( \Omega \). Then transitions from \( x \) to \( y \) occur according to \( p(x, y) \), and transitions from \( x \) to \( x \) occur with probability \( r(x) \). In the case that \( r(x) = 0 \), the integral of \( p(x, y) \) over \( y \) is 1 and the function \( p(x, y) \) may be referred to as the transition density of the chain. Note that

\[
P(x, A) = \int_A P(x, dy).
\]

The transition kernel is thus the distribution of \( \Phi_{i+1} \) given that \( \Phi_i = x \). The \( n \)th step ahead transition kernel is given by

\[
P^{(n)}(x, A) = \int_\Omega P(x, dy)P^{(n-1)}(y, A),
\]

where \( P^{(1)}(x, dy) = P(x, dy) \). Under certain conditions, which are discussed later, it can be shown that the \( n \)th iterate of the transition kernel (as \( n \to \infty \)) converges to the invariant distribution, \( \pi^* \). The invariant distribution satisfies
\[ \pi^*(dy) = \int_0^1 P(x,dy) \pi(x)\nu(dx), \tag{3} \]

where \( \pi \) is the density of \( \pi^* \) with respect to the measure \( \nu \) (thus, \( \pi^*(dy) = \pi(y)\nu(dy) \)). The invariance condition states that if \( \Phi_i \) is distributed according to \( \pi^* \), then so are all subsequent elements of the chain. A chain is said to be reversible if the function \( p(x,y) \) in (1) satisfies

\[ f(x)p(x,y) = f(y)p(y,x), \tag{4} \]

for a density \( f(\cdot) \). If this condition holds, it can be shown that \( f(\cdot) = \pi(\cdot) \).

A reversible chain has \( \pi^* \) as an invariant distribution (see Tierney, 1994; Chib and Greenberg, 1994b). An important notion is \( \pi^* \)-irreducibility. A Markov chain is said to be \( \pi^* \)-irreducible if, for every \( x \in \Omega \), \( \pi^*(A) > 0 \Rightarrow P(\Phi_i \in A | \Phi_0 = x) > 0 \) for some \( i \geq 1 \). This condition states that all sets with positive probability under \( \pi^* \) can be reached from any starting point in \( \Omega \).

Another important property of a chain is aperiodicity, which ensures that the chain does not cycle through a finite number of sets. A Markov chain is aperiodic if there exists no partition of \( \Omega = (D_0, D_1, \ldots, D_{p-1}) \) for some \( p \geq 2 \) such that \( P(\Phi_i \in D_{\text{mod}(p)} | \Phi_0 \in D_0) = 1 \) for all \( i \).

These definitions allow us to state the following (ergodicity) result (see Tierney, 1994), which forms the basis for MCMC methods.

**PROPOSITION 1.** If \( P(\cdot, \cdot) \) is \( \pi^* \)-irreducible and has invariant distribution \( \pi^* \), then \( \pi^* \) is the unique invariant distribution of \( P(\cdot, \cdot) \). If \( P(\cdot, \cdot) \) is also aperiodic, then for \( \pi^* \)-almost every \( x \in \Omega \) and all sets \( A \), we have the following:

1. \( \lim_{m \to \infty} |P^m(x,A) - \pi^*(A)| = 0 \)
2. For all \( \pi^* \)-integrable real-valued functions \( h \),

\[ \frac{1}{m} \sum_{i=1}^m h(\Phi_i) \to \int h(x)\pi(x)\nu(dx) \quad \text{as} \quad m \to \infty, \text{a.s.} \]

The first part of this theorem tells us that (under the stated conditions) the probability density of the \( m \)th iterate of the Markov chain is, for large \( m \), very close to its unique, invariant density. This means that if drawings are made from \( P^m(x,dy) \), then for large \( m \) the probability distribution of the drawings is the invariant distribution, regardless of the initial value. The second part states that averages of functions evaluated at sample values (ergodic averages) converge (as \( m \to \infty \), almost surely) to their expected value under the target density. Sufficient conditions for \( \pi^* \)-irreducibility and aperiodicity are presented later for the Gibbs and MH algorithms.

### 2.2. Gibbs Sampling

As already noted, the objective in MCMC simulation is to find a transition density that has the target density as its invariant distribution. One strategy
is the Gibbs sampling algorithm, in which the random vector is partitioned into several blocks and the transition density is defined as the product of the set of full conditional densities (the conditional density of each block given the data and the remaining parameters). The next item in the Markov chain is obtained by successively sampling the full conditional densities, given the most recent values of the conditioning parameters. Casella and George (1992) provide an elementary introduction. The value of this algorithm arises from the fact that in many applications the full conditional densities (perhaps after the parameter space has been augmented by latent data) take convenient forms and can be simulated even though the target density is intractable.

Suppose \( \pi (x) \), \( x \in \mathbb{R}^p \), is the (perhaps unnormalized) target density that we wish to sample. For some decomposition of \( x \) into \( x_1, \ldots, x_d \), let the full conditional density of the \( k \)th block be denoted by \( \pi (x_k | x_1, \ldots, x_{k-1}, x_{k+1}, \ldots, x_d) \). Then the Gibbs sampling algorithm is defined by the following iterations:

1. Specify starting values \( x^{(0)} = (x_1^{(0)}, \ldots, x_d^{(0)}) \), and set \( i = 0 \).
2. Simulate
   
   - \( x_1^{(i+1)} \) from \( \pi (x_1 | x_2^{(i)}, \ldots, x_d^{(i)}) \)
   - \( x_2^{(i+1)} \) from \( \pi (x_2 | x_1^{(i+1)}, x_3^{(i)}, \ldots, x_d^{(i)}) \)
   - \( x_3^{(i+1)} \) from \( \pi (x_3 | x_1^{(i+1)}, x_2^{(i+1)}, x_4^{(i)}, \ldots, x_d^{(i)}) \)
   - \( \ldots \)
   - \( x_d^{(i+1)} \) from \( \pi (x_d | x_1^{(i+1)}, x_2^{(i+1)}, \ldots, x_{d-1}^{(i+1)}) \).
3. Set \( i = i + 1 \), and go to step 2.

This algorithm thus provides the next item of the Markov chain \( x^{(i+1)} \) by simulating each of the full conditional densities, where the conditioning elements are revised during a cycle. In this case, \( r(x) = 0 \), and transitions of the chain from \( x = x^{(i)} \) to \( y = x^{(i+1)} \) (two distinct points) take place according to the transition density

\[
p_G (x, y) = \prod_{k=1}^d \pi (y_k | y_1, \ldots, y_{k-1}, x_k+1, \ldots, x_d).
\]  

Note that this transition density satisfies invariance condition (3): Suppose \( \nu \) is the Lebesgue measure; then, \( \int p_G (x, y) \pi (x) \, dx \) is

\[
\int \ldots \int \prod_{k=1}^d \frac{\pi (y_k | y_1, \ldots, y_{k-1}) \pi (x_{k+1}, \ldots, x_d | y_1, \ldots, y_k)}{\pi (x_{k+1}, \ldots, x_d | y_1, \ldots, y_{k-1})} \times \pi (x_1 | x_2, \ldots, x_d) \pi (x_2, \ldots, x_d) \, dx
\]

by applying Bayes theorem to each term in the transition kernel, letting \( y_0 \) denote the empty set, and writing \( \pi (x) \) as \( \pi (x_1 | x_2, \ldots, x_d) \pi (x_2, \ldots, x_d) \). The calculation is completed by noting that (i) the terms \( \pi (y_k | y_1, \ldots, y_{k-1}) \)
are independent of \( x \), so they factor out as \( \prod_{k=1}^{d} \pi \left( y_k \mid y_1, \ldots, y_{k-1} \right) \) to give \( \pi(y) \); (ii) the integral over \( x_1 \) is 1; (iii) the term \( \pi(x_2, \ldots, x_d) \) cancels with the denominator for \( k = 1 \); and (iv) cancellation by telescoping occurs because the numerator element in term \( k - 1 \) is \( \pi(x_{k+1}, \ldots, x_d \mid y_1, \ldots, y_{k-1}) \) after the requisite integration over \( x_k \), which cancels with the denominator in term \( k \).

We now turn to some issues that arise in implementing the Gibbs sampling algorithm. First, in designing the blocks, highly correlated components should be grouped together; otherwise, the Markov chain is likely to display autocorrelations that decay slowly, resulting in slow convergence to the target density (see Liu, Wong, and Kong, 1994; Section 3.3). Second, a tractable full conditional structure can sometimes be obtained by introducing latent or missing data into the definition of \( x \). The idea of adding variables to the sampler, known as “data augmentation,” was introduced by Tanner and Wong (1987) and is illustrated in several of the examples in Section 3.6.

Finally, if some of the full conditional densities are difficult to sample by traditional means (by the method of rejection sampling or by a known generator, e.g.), that density can be sampled by the MH algorithm (Müller, 1991) or a method that generates independent samples (Gilks and Wild, 1992).

Several sets of sufficient conditions ensure that the Markov chain generated by the Gibbs sampler satisfies the conditions of Proposition 1. A convenient set is due to Roberts and Smith (1994, Theorem 2; see also Chan, 1993).

**Proposition 2.** Suppose that (i) \( \pi(x) > 0 \) implies there exists an open neighborhood \( N_x \) containing \( x \) and \( \epsilon > 0 \) such that, for all \( y \in N_x \), \( \pi(y) \geq \epsilon > 0 \); (ii) \( \int \pi(x) \, dx_k \) is bounded for all \( k \) and all \( y \) in an open neighborhood of \( x \); and (iii) the support of \( x \) is arc-connected. Then, \( p_G(x, y) \) satisfies the conditions of Proposition 1.

The intuition for these conditions (and their connection to \( \pi \)-irreducibility and aperiodicity) should be noted. The conditions ensure that each full conditional density is well defined and that the support of the density is not separated into disjoint regions so that once the chain moves into one such region it never leaves it. Although these are only sufficient conditions for the convergence of the Gibbs sampler, the conditions are extremely weak and are satisfied in most econometric applications.

### 2.3. MH Algorithm

The MH algorithm is a powerful MCMC method that can be used to sample an intractable distribution \( \pi^*(\cdot) \). A sequence of draws from that algorithm is obtained as follows: Given that the latest drawing has yielded the value \( x \), the next value in the sequence is generated by drawing a value \( y \) from
a candidate generating density \( q(x, y) \) (also called a proposal density). The
\( y \) thus generated is accepted with probability \( \alpha(x, y) \), where
\[
\alpha(x, y) = \min \left[ \frac{\pi(y)q(y, x)}{\pi(x)q(x, y)}, 1 \right]
\]
if \( \pi(x)q(x, y) > 0 \);
\[1\]
otherwise.
If the candidate is rejected, the next sampled value is taken to be the current
value.

Some important points should be noted. First, the calculation of \( \alpha(x, y) \)
does not require knowledge of the normalizing constant of \( \pi(\cdot) \). Second, if
the proposal density is symmetric, that is, \( q(x, y) = q(y, x) \), then the accep-
tance probability reduces to \( \pi(y)/\pi(x) \), which is the original formulation
of Metropolis et al. (1953). Finally, it can be shown that the Gibbs sampler
is a special case of the MH algorithm (see Chib and Greenberg, 1995b).

To understand the basis for this algorithm first note that the transition ker-
nel of this Markov chain is given by
\[
P_{\text{MH}}(x, dy) = q(x, y)\alpha(x, y) \, dy + \left[ 1 - \int_0^1 q(x, y)\alpha(x, y) \, dy \right] \delta_x(dy),
\]
which states that transitions from \( x \) to \( y \) (\( y \neq x \)) are made according to
\( p_{\text{MH}}(x, y) = q(x, y)\alpha(x, y) \), \( x \neq y \).

The function \( p_{\text{MH}}(x, y) \) satisfies reversibility condition (4). To see this, note that
\[
\pi(x)p_{\text{MH}}(x, y) = \pi(x)q(x, y)\alpha(x, y)
\]
\[
= \min [\pi(y)q(y, x), \pi(x)q(x, y)]
\]
which is clearly symmetric, as required. Thus, \( \pi^* \) is an invariant distribution
for \( P_{\text{MH}}(x, dy) \).

A useful sufficient condition for convergence of chains generated by the MH
algorithm can be based on Lemma 1.2 of Mengersen and Tweedie (1993).

PROPOSITION 3. If \( \pi(x) \) and \( q(x, y) \) are positive and continuous for
all \((x, y)\), then \( p_{\text{MH}}(x, y) \) satisfies the conditions of Proposition 1.

Further discussion of sufficient conditions may be found in Smith and
Roberts (1993) and Tierney (1994). While Proposition 2 implies convergence,
it is not informative about the speed of convergence. This aspect of the
theory is under active investigation, the main focus being on geometric ergo-
dicity. Some results may be found in the articles mentioned earlier in this
paragraph and in Roberts and Tweedie (1994).

We now turn briefly to the question of specifying the proposal density that
drives the MH algorithm. Several generic choices are discussed by Tierney
One possibility is to let the proposal density take the form \( q(x, y) = q(y - x) \), as, for example, when the candidate is drawn from a multivariate normal density centered at the current value \( x \). This is referred to as the random walk-based MH chain. Another possibility, suggested by Hastings (1970) and called the independence MH chain by Tierney (1994), is specified by letting \( q(x, y) = q(y) \), with the location and form of the density adjusted to ensure that the acceptance rate (the proportion of times a candidate value is accepted) is reasonable. What is reasonable depends on the context, but it is important that the proposal density be chosen so that the chain travels over the support of the target density. This may fail to occur, with a consequent undersampling of low probability regions, if the chain is near the mode and if candidates are drawn too close to the current value.

It is worth emphasizing that once a proposal density is specified the MH algorithm is a straightforward method of simulating a given target density, including an intractable full conditional density that may arise in implementing the Gibbs sampling algorithm. It is easy to show that this combination of Markov chains is itself a Markov chain with the correct invariant distribution. Specifically, consider the case of two blocks and suppose that the full conditional density \( \pi(y_2|x_2) \) can be sampled directly but that \( \pi(y_1|x_1) \) requires use of the MH algorithm. Under the assumption of Lebesgue measure, the transition kernel is then the product of \( \pi(y_1|x_2) \, dy_1 \) and the transition kernel of the MH step, which is given by \( p_{MH}(x_2, y_2|y_1) \, dy_2 + r(x_2|y_1) \delta_{x_2}(dy_2) \). Then,

\[
\int \int \pi(x_1, x_2) \pi(y_1|x_2) \, dy_1 \left[ p_{MH}(x_2, y_2|y_1) \, dy_2 + r(x_2|y_1) \delta_{x_2}(dy_2) \right] \, dx_1 \, dx_2
\]

\[
= \pi(x_2) \pi(y_1|x_2) \, dy_1 \left[ p_{MH}(x_2, y_2|y_1) \, dy_2 + r(x_2|y_1) \delta_{x_2}(dy_2) \right] \, dx_2
\]

\[
= \pi(y_1) \, dy_1 \int \pi(x_2|y_1)p_{MH}(x_2, y_2|y_1) \, dy_2 \, dx_2
\]

\[
+ \pi(y_2) \pi(y_1|y_2) \, dy_1 \, dy_2 \, r(y_2|y_1)
\]

\[
= \pi(y_1) \pi(y_2|x_1) \, dy_1 \, dy_2 \int p_{MH}(y_2, x_2|y_1) \, dx_2
\]

\[
+ \pi(y_1, y_2) \, dy_1 \, dy_2 \, r(y_2|y_1)
\]

\[
= \pi(y_1, y_2) \, dy_1 \, dy_2 (1 - r(y_2|y_1)) + \pi(y_1, y_2) \, dy_1 \, dy_2 \, r(y_2|y_1),
\]

and invariance is confirmed. The fourth line follows from the reversibility of the MH step \( \pi(x_2|y_1)p_{MH}(x_2, y_2|y_1) = \pi(y_2|y_1)p_{MH}(y_2, x_2|y_1) \). It is therefore not necessary to iterate the MH algorithm when an intractable full
conditional density is encountered; one value is generated from the MH procedure, followed by the next simulation step.

2.4. Implementation Issues

Single-run vs. multiple-run sampling. The literature has suggested two methods for generating a sample from an MCMC algorithm: the single chain and the multiple chain. In the multiple-chain method, the value at the end of a transient phase of \( N_0 \) drawings is taken as a draw from the target distribution and the process is repeated with a new starting value. This method is considered wasteful because it generates an independent sample at the cost of discarding \( N_0 \) drawings in each cycle. The multiple-run method has been superseded for the most part by the single-run method. Even though this scheme usually introduces strong positive correlation between parameter values at successive iterations, the correlation often dissipates quickly so that it is close to zero between the iterate at \( t \) and \( t + n_1 \), say, for moderate \( n_1 \).

Detection of convergence. Because the length of the transient phase seems to be model- and data-dependent, the question of convergence requires considerable care. If the target density being simulated is “well behaved” (as it is in many standard econometric models), then the simulated Markov chain usually mixes rapidly and the serial correlations die out quickly. But with weak identifiability of the parameters and/or multiple modes the chain can be poorly behaved and slow to produce numerically accurate results. Many proposals have been made to shed light on these problems. One class of approaches (exemplified by Ritter and Tanner, 1992; Gelman and Rubin, 1992; Geweke, 1992; Zellner and Min, 1995) attempts to analyze the output to determine whether or not the chain has converged. The Gelman and Rubin approach, which is based on multiple-chain sampling from dispersed starting values, compares the within and between variation in the sampled values. The Ritter and Tanner approach, which requires a single run, monitors the ratio of the target density (up to a normalizing constant) and the current estimate of the target density; stability of the ratio indicates that the chain has converged. Another type of approach (e.g., Raftery and Lewis, 1992; Polson, 1994) attempts to produce estimates of the burn-in time prior to sampling by analyzing the rate of convergence of the Markov chain to the target density. Considerable work continues to be done in this important area, but no single approach appears to be adequate for all problems.

3. EXAMPLES

We now show how the MCMC simulation approach can be applied to a wide variety of econometric models, starting with a simple example in which the Gibbs sampler can be applied without data augmentation and where simu-
lation is from standard distributions only. The later examples require more of the methods already described. Our objectives are to present the logic of the method and to help the reader understand how to apply the method in other situations.

Before presenting the examples, we introduce the assumptions for prior densities that are used throughout this section: The vector \( \beta \) follows an \( \mathcal{N}_k(\beta_0, B_0^{-1}) \), the variance \( \sigma^2 \) is distributed as inverted gamma \( IG(\frac{v_0}{2}, \frac{b_0}{2}) \), and the precision matrix \( \Omega^{-1} \) follows a Wishart \( \mathcal{W}_p(\rho_0, R_0) \) distribution. Hyperparameters of the prior densities, subscripted by a 0, are assumed to be known. A density or distribution function is denoted by \( [ \cdot ] \), a conditional density or distribution by \( [ \cdot | \cdot ] \), and \( \overset{\equiv}{=} \) denotes equality in distribution.

3.1. The Seemingly Unrelated Regression Model

Our first example is the seemingly unrelated regression model, which is widely employed in econometrics. Under the assumption of normally distributed errors, the observed data \( y_{it} \) are generated by

\[
y_{it} = x_{it}^\prime \beta_i + \epsilon_{it}, \quad \epsilon_{it} = (\epsilon_{it1}, \ldots, \epsilon_{ipt})' \sim \text{i.i.d.} \mathcal{N}_p(0, \Omega),
\]

where \( \beta_i : k_i \times 1 \) and \( \Omega \) is a positive definite matrix. By stacking observations for each time period, we rewrite the model in vector form as \( y_t = X_t \beta + \epsilon_t \), where \( y_t = (y_{t1}, \ldots, y_{tp})' \), \( X_t = \text{diag}(x_{t1}, \ldots, x_{tp}) \), \( \beta = (\beta_1, \ldots, \beta_p)' : k \times 1 \), and \( k = \sum k_i \). We obtain the single equation Gaussian regression model when \( p = 1 \). It is well known that the maximum likelihood estimates for a sample of data \( Y_n = (y_1, \ldots, y_n) \) can be obtained only through an iterative procedure and that the finite sample distribution of these estimators is intractable. In contrast, the Gibbs sampling algorithm provides an exact, small-sample Bayesian analysis for this model (Percy, 1992; Chib and Greenberg, 1995a).

Suppose that prior information about \( (\beta, \Omega^{-1}) \) is represented by the density \( \pi(\beta) \pi(\Omega^{-1}) \), where we are assuming that \( \beta \) and \( \Omega^{-1} \) (the precision matrix) are independent. Then the posterior density of the parameters (proportional to the product of the prior density and the likelihood function) is given by

\[
\pi(\beta) \pi(\Omega^{-1}) \times |\Omega^{-1}|^{n/2} \exp \left[ -\frac{1}{2} \sum_{t=1}^{n} (y_t - X_t \beta)' \Omega^{-1} (y_t - X_t \beta) \right]
\]

This is the target density (with unknown normalizing constant) that must be simulated. Now note that if \( \beta \) and \( \Omega^{-1} \) are treated as two blocks of parameters, the full conditional densities, \( \beta | Y_n, \Omega^{-1} \) and \( \Omega^{-1} | Y_n, \beta \), are easy to simulate. In particular, under the priors already mentioned,

\[
\beta | Y_n, \Omega^{-1} \sim \mathcal{N}_k(\hat{\beta}, B_n^{-1}) \quad \text{and} \quad \Omega^{-1} | Y_n, \beta \sim \mathcal{W}_p(v_0 + n, R_n),
\]
where \( \hat{\beta} = B_n^{-1}(B_0\beta_0 + \sum_{i=1}^{n_i} X_i'\Omega^{-1}y_i) \), \( B_n = (B_0 + \sum_{i=1}^{n_i} X_i'\Omega^{-1}X_i) \), and \( R_n = \left[ R_0^{-1} + \sum_{i=1}^{n_i} (y_i - X_i\beta)(y_i - X_i\beta)' \right]^{-1} \). It is not difficult to verify the sufficient conditions mentioned in Proposition 2. Therefore, simulating these two distributions by the Gibbs algorithm yields a sample \( \{\beta^{(i)}, \Omega^{-1(i)}\} \) such that \( \beta^{(i)} \) is distributed according to the marginal density \( \pi(\beta | Y_n), \Omega^{-1(i)} \sim \pi(\Omega^{-1} | Y_n) \), and \( \{\beta^{(i)}, \Omega^{-1(i)}\} \) is distributed according to the target (joint) density. It should be noted that the sample of draws is obtained without an importance sampling function or the evaluation of the likelihood function.

### 3.2. Tobit and Probit Regression Models

In the previous example, the Gibbs sampler was applied directly to the parameters of the model. In other situations, a tractable set of full conditional distributions can be obtained by enlarging the parameter space with latent data, as we illustrate next for the tobit and probit models. Interestingly, while the parameter space over which the sampler is defined is extremely large (in the case of the probit model it is larger than the sample size), the number of blocks in the simulation is quite small (three in the tobit model and two in the binary probit model).

Consider the censored regression model of Tobin (1958), in which the observation \( y_i \) is generated by

\[ z_i \sim N(x_i'\beta, \sigma^2) \quad \text{and} \quad y_i = \max(0, z_i), \quad 1 \leq i \leq n. \]

Given a set of \( n \) independent observations, the likelihood function for \( \beta \) and \( \sigma^2 \) is

\[
\prod_{i \in C} \left[ 1 - \Phi(x_i'\beta/\sigma) \right] \prod_{i \in C'} (\sigma^{-2}) \exp\left[ -\frac{1}{2\sigma^2} (y_i - x_i'\beta)^2 \right],
\]

where \( C \) is the set of censored observations and \( \Phi \) is the c.d.f. of the standard normal random variable. Clearly, this function (after multiplication by the prior density) is difficult to simplify for use in the Gibbs sampling algorithm. In one of the first applications of Gibbs sampling in econometrics, Chib (1992b) shows that matters are simplified enormously if the parameter space is augmented by the latent data corresponding to the censored observations.

To see why, suppose we have available the vector \( z = (z_i), i \in C \). Let \( y_z \) be an \( n \times 1 \) vector with \( i \)th component \( y_i \) if the \( i \)th observation is not censored and \( z_i \) if it is censored. Now consider applying the Gibbs sampling algorithm with blocks \( \beta, \sigma^2 \), and \( z \) with the respective full conditional densities \( \{\beta | Y_n, z, \sigma^2\}, \{\sigma^2 | Y_n, z, \beta\}, \) and \( \{z | Y_n, \beta, \sigma^2\} \). These distributions are all tractable, and the Gibbs simulation is readily applied. The first two distributions reduce to

\[
\beta | y_z, \sigma^2 \sim N_k(\hat{\beta}, (B_0 + \sigma^{-2}X'X)^{-1})
\]
and
\[
o^2 | y_2, \beta \sim g\left(\frac{\nu_0 + n}{2}, \frac{\delta_0 + \delta_2}{2}\right),
\]
where \( X = (x_1, \ldots, x_n)' \), \( \hat{\beta} = (B_0 + \sigma^{-2} X'X)^{-1}(B_0 \beta_0 + \sigma^{-2} X'y) \), and \( \delta_n = (y_2 - X\hat{\beta})' (y_2 - X\hat{\beta}) \), while the full conditional distribution of the latent data simplifies into the product of \( n \) independent distributions, \( [z | y_n, \beta, \sigma^2] = \prod_{i \in \mathcal{C}} [z_i | y_i = 0, \beta, \sigma^2] \), where
\[
z_i | y_i = 0, \beta, \sigma^2 \sim T_N(-\infty, 0) (x_i'\beta, \sigma^2), \quad i \in \mathcal{C},
\]
a truncated normal distribution with support \((-\infty, 0]\). The simplification to conditional independence observed in this case (e.g., the distributions of \( \beta \) and \( \sigma^2 \) are independent of the censored data given the latent data) usually occurs with data augmentation, which explains why data augmentation is such a useful tool (Morris, 1987).

The value of data augmentation is also clear in the probit model, where we are given \( n \) independent observations \( Y_n = (y_i) \), each \( y_i \) being distributed Bernoulli with \( \Pr(y_i = 1) = \Phi(x_i'\beta) \). For this model and many others in this class, Albert and Chib (1993a) developed a simple and powerful approach that introduces latent Gaussian data as additional unknown parameters in a Gibbs sampling algorithm. They exploit the fact that the specification
\[
z_i = x_i'\beta + u_i, \quad u_i \sim \text{i.i.d. } N(0,1), \quad \text{and } y_i = I[z_i > 0]
\]
produces the probit model. The Gibbs sampling algorithm (with data augmentation) is now defined through the full conditional distributions
\[
[\beta | Y_n, Z_n] \overset{d}{=} [\beta | Z_n] \quad \text{and} \quad [Z_n | Y_n, \beta] \overset{d}{=} \prod_{i=1}^n [z_i | y_i, \beta],
\]
where \( Z_n = (z_1, \ldots, z_n)' \).

The full conditional distribution of \( \beta \) has the same form as (7) with \( y_2 \) replaced by \( Z_n \) and \( \sigma^2 = 1 \). The full conditional \([Z_n | Y_n, \beta] \), which factors into the product of independent terms, depends on whether \( y_i = 1 \) or \( y_i = 0 \). From (8), we have \( z_i \leq 0 \) if \( y_i = 0 \) and \( z_i > 0 \) if \( y_i = 1 \). Thus,
\[
z_i | y_i = 0, \beta \sim T_N(-\infty, 0) (x_i'\beta, 1),
\]
\[
z_i | y_i = 1, \beta \sim T_N(0, \infty) (x_i'\beta, 1), \quad 1 \leq i \leq n.
\]

This MCMC algorithm can be easily modified to estimate a model with an independent student-\( t \) link function with \( \nu \) degrees of freedom (see Albert and Chib, 1993a). From the result that the \( t \)-distribution is a scale mixture of normals with mixing distribution Gamma\( \left(\frac{\nu}{2}, \frac{\nu}{2}\right) \), it is possible to augment the parameter space further by these gamma variables, one for each observation. The full conditionals are again tractable (for use of this idea in lin-
ear regression, see also Carlin and Polson, 1991; Geweke, 1993b). Albert and Chib (1993a) also let \( \nu \) be unknown, which leads to a general robustification of the probit model.

### 3.3. State-Space Model

We next consider the state-space model (Harvey, 1981) in which the observation vector \( y_t \) is generated by

\[
y_t = X_t \theta_t + \epsilon_t, \quad \epsilon_t \sim \text{i.i.d. } \mathcal{N}_p(0, \Omega), \quad 1 \leq t \leq n,
\]

and the state vector \( \theta_t : m \times 1 \) evolves according to the Markov process

\[
\theta_t = G \theta_{t-1} + \eta_t, \quad \eta_t \sim \text{i.i.d. } \mathcal{N}_m(0, \Psi). \tag{9}
\]

In the frequentist approach, the unknown parameters \((\Omega, G, \Psi)\) are estimated by maximum likelihood, and inferences on the states are conducted through the Kalman filter and smoothing recursions, given the estimated parameters. A full Bayes approach for the nonlinear version of this model is developed by Carlin, Polson, and Stoffer (1992) and for the present linear case by Carter and Kohn (1994), Chib (1992a), Frühwirth-Schnatter (1994) and Chib and Greenberg (1995a). For important recent developments, see de Jong and Shephard (1995). We illustrate the case of known \( G \), but the procedure can be extended to deal with an unknown \( G \).

From the previous examples it is clear that the \( \theta_t \) should be included in the Gibbs sampler, but this may be done either through the distributions

\[
[\theta_s \mid Y_n, \Omega, \Psi, \theta_{s \neq t}], \quad [\Omega \mid Y_n, \{\theta_t\}, \Psi], \quad [\Psi \mid Y_n, \{\theta_t\}, \Omega], \tag{10}
\]

or through the distributions

\[
[\theta_0, \ldots, \theta_n \mid Y_n, \Omega, \Psi], \quad [\Omega \mid Y_n, \{\theta_t\}, \Psi], \quad [\Psi \mid Y_n, \{\theta_t\}, \Omega]. \tag{11}
\]

The two samplers differ in the way they simulate the \( \theta_t \)'s. In (10) the states are simulated from their individual full conditional distributions, whereas in (11) they are sampled from their joint full conditional distribution. Because the \( \theta_t \) are correlated (they follow a Markov process), the blocking in (11) will lead to faster convergence to the target distribution and is therefore preferred.

The Gibbs sampler proceeds as follows: If the state vectors are known, the full conditional distributions for \( \Omega^{-1} \) and \( \Psi^{-1} \) are given by

\[
\Omega^{-1} \mid Y_n, \{\theta_t\} \sim \mathcal{W}_p \left( \rho_0 + n, \left[ R_0^{-1} + w \sum_{i=1}^{n} (y_i - X_i \theta_i)(y_i - X_i \theta_i)' \right]^{-1} \right),
\]

\[
\Psi^{-1} \mid Y_n, \{\theta_t\} \sim \mathcal{W}_m \left( \delta_0 + n, \left[ D_0^{-1} + w \sum_{i=1}^{n} (\theta_i - G \theta_{i-1})(\theta_i - G \theta_{i-1})' \right]^{-1} \right),
\]

where \( \delta_0 \) and \( D_0 : m \times m \) are the parameters of the Wishart prior for \( \Psi^{-1} \). These are both standard distributions.
For the simulation of the \( \{ \theta_t \} \), let \( \psi = (\Omega, \Psi) \) and \( Y_t = (y_1, \ldots, y_t) \). By writing the joint density of \( \{ \theta_t \} \) in reverse time order,

\[
p(\theta_n | Y_n, \psi) \times p(\theta_{n-1} | Y_n, \theta_n, \psi) \times \cdots \times p(\theta_0 | Y_n, \theta_1, \ldots, \theta_n, \psi),
\]

we can see how to obtain a draw from the joint distribution: Draw \( \tilde{\theta}_n \) from \( [\theta_n | Y_n, \psi] \); then draw \( \tilde{\theta}_{n-1} \) from \( [\theta_{n-1} | Y_n, \theta_n, \psi] \), and so on, until \( \tilde{\theta}_0 \) is drawn from \( [\theta_0 | Y_n, \theta_1, \ldots, \theta_n, \psi] \). We now show how to derive the density of the typical term in (12), \( p(\theta_t | Y_n, \theta_{t+1}, \ldots, \theta_n, \psi) \).

Let \( \theta^* = (\theta_s, \ldots, \theta_n) \) and \( Y^* = (y_s, \ldots, y_n) \) for \( s \leq n \). Then,

\[
p(\theta_t | Y_n, \theta_{t+1}, \ldots, \theta_n, \psi) \propto p(\theta_t | Y_t, \psi) p(\theta_{t+1} | Y_t, \theta_t, \psi) f(\theta_{t+1} | \theta_t, \psi) \frac{f(Y_{t+1}, \theta_{t+1} | Y_t, \theta_t, \psi)}{f(Y_{t+1} | \theta_t, \psi)},
\]

from (9) and the fact that \( (Y_{t+1}, \theta_{t+1}) \) is independent of \( \theta_t \) given \( (\theta_{t+1}, \psi) \). The first density is Gaussian with moments \( \hat{\theta}_t \) and \( R_t \), which are obtained by running the recursions \( \hat{\theta}_{t+1} = G\hat{\theta}_{t+1} - K_t (y_t - X_t \hat{\theta}_t) \) and \( R_{t+1} = (I - K_t X_t) R_t M_t R_{t+1} \), where \( \hat{\theta}_{t+1} = G\hat{\theta}_{t+1} - K_t F_t R_t \), and \( R_t = GR_t R_{t+1} R_t \). The second density is Gaussian with moments \( \hat{\theta}_t \) and \( \Psi \). Completing the square in \( \theta_t \) leads to the following algorithm to sample \( \{ \theta_t \} \):

1. Run the Kalman filter and save its output \( \{ \hat{\theta}_t, R_t, M_t \} \), where \( R_t = R_t M_t R_{t+1} M_t \) and \( M_t = R_t R_{t+1} M_t \).
2. Simulate \( \tilde{\theta}_n \) from \( N_m(\hat{\theta}_n, R_n) \); then simulate \( \tilde{\theta}_{n-1} \) from \( N_m(\hat{\theta}_{n-1}, R_{n-1}) \), and so on, until \( \tilde{\theta}_0 \) is simulated from \( N_m(\hat{\theta}_0, R_0) \), where \( \hat{\theta}_t = \hat{\theta}_t + M_t (\hat{\theta}_{t+1} - \hat{\theta}_t) \).

3.4. Regression Models with AR(p) Errors

This subsection illustrates a simulation in which the MH algorithm is used. A detailed analysis of the regression model with ARMA(p,q) errors may be found in Chib and Greenberg (1994) and Marriott, Ravishanker, and Gel- fand (1995).

Consider the model

\[
y_t = X_t \beta + \epsilon_t, \quad t = 1, \ldots, n,
\]

where \( y_t \) is a scalar observation. Suppose that the error is generated by the stationary AR(p) process

\[
\epsilon_t - \phi_1 \epsilon_{t-1} - \cdots - \phi_p \epsilon_{t-p} = u_t \quad \text{or} \quad \phi(L) \epsilon_t = u_t,
\]

where \( u_t \sim \text{i.i.d. } \mathcal{N}(0, \sigma^2) \) and \( \phi(L) = 1 - \phi_1 L - \cdots - \phi_p L^p \) is a polynomial in the lag operator \( L \). The stationarity assumption implies that the roots of \( \phi(L) \) lie outside the unit circle; this constrains \( \phi = (\phi_1, \ldots, \phi_p) \) to lie in a subset \( S_p \) of \( \mathbb{R}^p \). To conform to this constraint, we take the prior of \( \phi \) to be \( \mathcal{N}_p(\phi_0, \Psi_0^{-1}) I_{S_p} \), a normal distribution truncated to the
stationary region (and assume the standard prior distributions for $\beta$ and $\sigma^2$).

The likelihood function for this model can be expressed as

$$f(Y_n | \beta, \phi, \sigma^2) = \Psi(\phi) \times (\sigma^2)^{-(n-p)/2} \exp \left[ -\frac{1}{2\sigma^2} \sum_{i=p+1}^{n} (y_i^* - x_i^* \beta)^2 \right],$$

where, for $t \geq p + 1$, $y_i^* = \phi(L)y_i$, $x_i^* = \phi(L)x_i$, and

$$\Psi(\phi) = (\sigma^2)^{-p/2} |\Sigma_p|^{-1/2} \exp \left[ -\frac{1}{2\sigma^2} (Y_p - X_p \beta)' \Sigma_p^{-1} (Y_p - X_p \beta) \right]$$

is the (stationary) density of the first $p$ observations. In the preceding, $Y_p = (y_1, \ldots, y_p)'$, $X_p = (x_1, \ldots, x_p)'$, and $\Psi = \phi \Sigma_p \phi' + e_1(p)e_1(p)'$, with

$$\Phi = \begin{bmatrix} \Phi_{-p} & \phi_p \\ I_{p-1} & 0 \end{bmatrix},$$

$e_1(p) = (1,0, \ldots, 0)'$, and $\Phi_{-p} = (\phi_1, \ldots, \phi_{p-1})'$.

How can the posterior density be simulated? The answer lies in recognizing three facts. First, the Gibbs strategy is useful for this problem by taking $\beta$, $\phi$, and $\sigma^2$ as blocks. Second, the full conditional distributions of $\beta$ and $\sigma^2$ can be obtained easily after combining the two exponential terms in the sampling density. Third, the full conditional of $\phi$ can be simulated with the MH algorithm. We next provide some of the details.

Define $Y_p^* = Q^{-1}Y_p$ and $X_p^* = Q^{-1}X_p$, where $Q$ satisfies $QQ' = \Sigma_p$. Let $y^* = (y_1^*, \ldots, y_p^*)'$ and likewise for $X^*$. Finally, let $e = (e_{p+1}, \ldots, e_n)'$, and let $E$ denote the $n - p \times p$ matrix with the $t$th row given by $(e_{t-1}, \ldots, e_{t-p})$, where $e_t = y_t - x_t \beta$, $t \geq p + 1$. It is now not difficult to show that the full conditional distributions are

$\beta | Y_n, \phi, \sigma^2 \sim \mathcal{N}(\hat{\beta}, B_n^{-1})$

$\phi | Y_n, \beta, \sigma^2 \propto \Psi(\phi) \times \mathcal{N}(\Phi, \Phi_n^{-1})I_{S_n},$

$\sigma^2 | Y_n, \beta, \phi \sim \mathcal{G} \left( \frac{v_0 + n}{2}, \frac{\delta_0 + d_0}{2} \right),$

where $\hat{\beta} = B_n^{-1}(B_0\beta_0 + \sigma^{-2}X^*y^*)$, $B_n = (B_0 + \sigma^{-2}X^*X^*), d_0 = |y^* - X^*\beta|^2$, $\hat{\phi} = \Phi_n^{-1}(\Phi_0\phi_0 + \sigma^{-2}E'e)$, and $\Phi_n = (\Phi_0 + \sigma^{-2}E'E)$.

The full conditionals of $\beta$ and $\sigma^2$ are easily simulated. To simulate $\phi$, we can employ the MH independence chain with $\mathcal{N}(\Phi, \Phi_n^{-1})I_{S_n}$ as the candidate generating density. Then the MH step is implemented as follows. At the $i$th iteration, draw a candidate $\phi^{(i+1)}$ from a normal density with mean $\hat{\phi}$ and covariance $\sigma^2(\iota)\Phi_n^{-1}$; if it satisfies stationarity, we move to this point with probability

$$\min \left\{ \frac{\Psi(\phi^{(i+1)})}{\Psi(\phi^{(i)})}, 1 \right\}$$
3.5. Other Models

Other models in addition to those already illustrated lend themselves to MCMC methods and to Gibbs sampling with data augmentation in particular. In the regression framework, missing data can be added to the sampler to generate samples from distributions of the parameters. The important class of multinomial probit models can be analyzed by MCMC simulation (through data augmentation), as discussed by Albert and Chib (1993a), McCulloch and Rossi (1994), and Geweke, Keane, and Runkle (1994). McCulloch and Rossi (1994) provide an extensive discussion, with examples, of the benefits of Gibbs sampling in this context. For applications to generalized linear models with random effects, see Zeger and Karim (1991). Another important area is that of mixture models, in which each observation in the sample can arise from one of K different populations. Two types of models have been investigated. In the first, the populations are sampled independently from one observation to the next (Diebolt and Robert, 1994). In the second, the populations are sampled according to a Markov process, which is the Markov switching model (Albert and Chib, 1993b; Chib, 1993b). New econometric applications that illustrate the versatility of MCMC methods continue to appear: reduced rank regressions (Geweke, 1993a), stochastic volatility models (Jacquier, Polson, and Rossi, 1994), cost functions (Koop, Osiewalski, and Steel, 1994), censored autoregressive data (Zangari and Tsurumi, 1994), and many others.

4. INFERENCE WITH MCMC METHODS

We next examine ways in which a sample generated by MCMC methods can be used for statistical inference, including estimation of moments and marginal densities, prediction, sensitivity, model adequacy, and estimation of modes.

4.1. Estimation of Moments and Numerical Standard Errors

An implication of Proposition I is that output from the MCMC simulation can be used to estimate moments, quantiles, and other summaries of the target density. The quantity $\hat{h} = \int h(\psi) \pi(\psi | Y_n) d\psi$, for integrable $h$, where $\psi$ denotes parameters and latent data, is estimated by the ergodic average

$$\hat{h} = M^{-1} \sum_{i=1}^{M} h(\psi^{(i)}).$$

and otherwise set $\phi^{(i+1)} = \phi^{(i)}$. Chib and Greenberg (1994) verify the sufficient conditions for the convergence of this algorithm and provided several empirical examples.
The numerical standard error of this estimate (the variation that can be expected in \( \hat{h} \) if the simulation were to be repeated) is estimated as follows. If \( Z_i = h(\psi^{(i)}) \), then

\[
\text{var}(\hat{h}) = M^{-2} \sum_{j,k} \text{cov}(Z_j, Z_k)
\]

\[
= \sigma^2 M^{-2} \sum_{j,k=1}^{M} \rho_{|j-k|}
\]

\[
= \sigma^2 M^{-1} \left[ 1 + 2 \sum_{s=1}^{M} \left( 1 - \frac{s}{M} \right) \rho_s \right],
\]

where \( \rho_s = \text{corr}(Z_i, Z_{i-s}) \) and \( \sigma^2 = \text{var}(Z_i) \) (see Ripley, 1987, Ch. 6). Note this variance is larger than \( \sigma^2/M \) (the variance under independent sampling) if all the \( \rho_s > 0 \), as is frequently the case. The variance can also be shown to equal \( \tau^2/M \), where \( \tau^2 = 2\pi f(0) \) and \( f(\cdot) \) is the spectral density of \( \{Z_i\} \). Many methods have been proposed to estimate the variance efficiently; Geweke (1992), for example, estimates the spectral density at frequency zero, whereas McCulloch and Rossi (1994) use the approach of Newey and West (1987) (see also Geyer, 1992). An equivalent, more traditional approach is based on the method of "batch means." The data \( \{Z_i\} \) are batched or sectioned into \( k \) subsamples of length \( m \) with means \( \{B_i\} \) and the variance of \( \hat{h} \) estimated as \( [k(k-1)]^{-1} \sum (B_i - \bar{B})^2 \). The batch length \( m \) is chosen large enough that the first-order serial correlation between batch means is less than 0.05.

### 4.2. Marginal Density Estimates

Marginal and joint density functions of components of \( \psi \) can be readily computed from the posterior output. For example, the marginal density of \( \psi_i \) can be estimated via a histogram of the simulated values \( \{\psi_i^{(i)}\} \). In addition, the histogram estimate can be smoothed by standard kernel methods. Note that if the full conditional density \( \pi(\psi_1 | Y_n, \psi_2, \ldots, \psi_{a}) \) is available (for some partition of the parameter vector), then \( \pi(\psi_1 | Y_n) \) at the point \( \psi_1^* \) can also be estimated as

\[
\hat{\pi}(\psi_1^* | Y_n) = M^{-1} \sum_{i=1}^{M} \pi(\psi_1^* | Y_n, \psi_2^{(i)}, \ldots, \psi_{a}^{(i)}),
\]

because \( \{\psi_2^{(i)}, \ldots, \psi_{a}^{(i)}\} \) is a sample from the marginal density \( \pi(\psi_2, \ldots, \psi_{a} | Y_n) \). Gelfand and Smith (1990) refer to (19) as "Rao–Blackwellization," and Liu et al. (1994) show that this mixture approximation to the marginal density generally produces estimates with a smaller numerical standard error than the empirical estimator. They also find that it is preferable to calculate \( \int h(\psi_1) \pi(\psi | Y_n) \, d\psi \) by averaging \( E(h(\psi_1) | Y_n, \psi_2, \ldots, \psi_{a}) \), if the latter is available, over the simulated draws of \( (\psi_2, \ldots, \psi_{a}) \).
4.3. Predictive Inference

Recall that the Bayesian predictive density is given by

\[ f(Y_f | Y_n) = \int f(Y_f | Y_n, \psi) \pi(\psi | Y_n) \, d\psi, \]

where \( f(Y_f | Y_n, \psi) \) is the conditional density of the future observations given \( \psi \). This density can be sampled easily by the method of composition: For each \( \psi^{(i)} \), simulate the vector \( y_f^{(i)} \) from the density \( f(y_f | Y_n, \psi^{(i)}) \). Then, \( \{y_f^{(i)}\} \) constitutes the desired sample. Albert and Chib (1993b) used this approach to sample and summarize the four-step ahead prediction density for autoregressive models with Markov switching.

4.4. Sensitivity Analysis

The simulation output can also be used to determine the sensitivity of the estimate in (18) to changes in the prior distribution without rerunning the MCMC simulation. This can be done by the method of sampling-importance-resampling (Rubin, 1988). Specifically, given a sample \( \psi^{(1)}, \ldots, \psi^{(M)} \) from \( \pi(\psi | Y_n) \), a sample of \( m \) draws from a posterior density \( p(\psi | Y_n) \) that corresponds to a different prior density can be obtained by resampling the original draws with weights \( w(\psi_i) \propto [p(\psi^{(i)} | Y_n)] / [\pi(\psi^{(i)} | Y_n)] \), \( i = 1, \ldots, M \). The resampled values, which are distributed according to \( p(\cdot | \cdot) \) as \( M/m \to \infty \), can be used to recompute \( \hat{h} \). Other model perturbations can be similarly analyzed (Gelfand and Smith, 1992).

4.5. Evaluation of Model Adequacy

The marginal likelihood is a central quantity in the comparison of Bayesian models. If the models are defined as \( H_k = \{f(Y_n | \psi_k), \pi(\psi_k)\} \), where \( \psi_k \) is the parameter vector for the \( k \)th model, then the marginal likelihood for model (or hypothesis) \( H_k \) is defined as

\[ m(Y_n | H_k) = \int f(Y_n | \psi_k) \pi(\psi_k) \, d\psi_k, \]

which is the integral of the sampling density w.r.t. to the prior density. The evidence in the data for any two models \( M_k \) and \( M_l \) is summarized by the Bayes factor \( B_{kl} = m(Y_n | H_k) / m(Y_n | H_l) \), or by the posterior odds \( O_{kl} = B_{kl} \times (p_k / p_l) \), where \( p_k \) is the prior probability of \( M_k \) (Leamer, 1978; Zellner, 1984).

Two distinct methods have been used to compute \( B_{kl} \) (for a comprehensive review, see Kass and Raftery, 1994). In the first approach (Newton and Raftery, 1994; Chib, 1995), \( m(Y_n | H_k) \) is computed directly from the MCMC output corresponding to model \( M_k \). In the second approach (Carlin and Chib, 1995), a model indicator \( M, M \in \{1, \ldots, K\} \), is defined, and a Gibbs sampler is constructed from the full conditional distributions \( [\psi_1, \ldots, \psi_K | Y_n, M] \) and \( [M | Y_n, \psi_1, \ldots, \psi_K] \). The posterior relative frequencies of \( M \) are used to
compute posterior model probabilities and thence the Bayes factors for any two models. A related approach for models with a common parameter \( \psi \) is considered by Carlin and Polson (1991) and George and McCulloch (1993).

4.6. Modal Estimates

Markov chain methods can be used to find the modal estimates in models with missing or latent data. This is achieved by sampling the latent or missing data and then evaluating the E step in the EM algorithm using the simulated draws (Celeux and Diebolt, 1985; Wei and Tanner, 1990; Ruud, 1991).

Given the current estimate of the maximizer \( \theta^{(i)} \), define

\[
Q(\theta, \theta^{(i)}) = \int \log(\pi(\theta | Y_n, Z_n))d[Z_n | Y_n, \theta^{(i)}],
\]

where \( Y_n \) is the observed data and \( Z_n \) is the latent data. To avoid what is usually an intractable integration, given parameter values we can draw a sample \( Z_{n,j}, j \leq N \), by MCMC and approximate \( Q \) by \( \hat{Q}(\theta, \theta^{(i)}) = N^{-1} \sum_j \log(\pi(\theta | Y_n, Z_{n,j})) \). In the M step, \( \hat{Q} \) is maximized over \( \theta \) to obtain the new parameter \( \theta^{(i+1)} \). These steps are repeated until the difference \( \| \theta^{(i+1)} - \theta^{(i)} \| \) is negligible. When producing the sequence \( \{ \theta^{(i)} \} \), it is usual to begin with a small value of \( N \) and let the number of replications of \( Z_n \) increase as the maximizer is approached. This procedure is applied to finite mixture distributions with Markov switching in Chib (1993b) and to partial non-Gaussian state-space models in Shephard (1994).

5. Conclusions

Our survey of developments in the theory and practice of MCMC methods, with an emphasis on applications to econometric problems, has shown how these algorithms combined with data augmentation can be used to organize a systematic approach to Bayesian inference. We have illustrated the ideas in the context of models with censoring, discrete responses, panel data, autoregressive errors, and time-varying parameters, but the ideas can be applied to many other econometric models. For frequentist econometricians, we have shown how Monte Carlo versions of the EM algorithm can be used to find the posterior mode.

One of the considerable arguments in favor of MCMC methods (and for simulation-based inference in general) is that they make possible the analysis of models that are difficult to analyze by other means. No longer is analysis in the Bayesian context restricted to tightly specified models and prior distributions. As we have shown, many models, including those with intractable likelihood functions, can be simulated by MCMC methods. Various inference questions, especially those relating to prediction, model and prior
perturbations, and model adequacy can be addressed effectively using the output of the simulation.

MCMC methods have already proved extremely useful in econometrics, and more applications continue to appear at a rapid rate. These developments have been enormously aided by significant improvements in computer hardware and software. Great opportunities remain for the work that still needs to be done, especially in the form of applications to new and existing problems and theoretical developments on the speed of convergence, sufficient conditions for validity, and tuning of methods.

NOTES

1. Work by Smith and Roberts (1993) and Tanner (1993) contain valuable surveys of some of the same ideas but are addressed to a general statistical audience. We emphasize econometric applications in the present paper.

2. This feature is shared by some non-MCMC methods (such as those based on rejection sampling) that are designed to sample a density (Rubinstein, 1981; Ripley, 1987).

3. By contrast, Monte Carlo methods with importance sampling (Kloek and van Dijk, 1978; Geweke, 1989; Koop, 1994) are difficult to apply in these situations due to the complexity of the likelihood function. In addition, the need to find a suitable importance sampling function is a limitation in high-dimensional problems.

4. For frequentist statisticians, these distributions can be regarded as proportional to the conditional likelihood functions of each parameter, where the conditioning is on values of all remaining parameters.

5. Note that the full conditional density is proportional to the joint density \( \pi(x) \). Deriving the former density is often straightforward.

6. The idea of data augmentation also appears in maximum likelihood estimation of missing data models by the EM algorithm (Dempster, Laird, and Rubin, 1977).

7. The multiple-modes case can be quite deceptive. The chain may appear to mix well but may actually be trapped in a subregion of the support. This example indicates the importance of understanding by analytical means the target density being simulated and then devising an algorithm to achieve a chain with desirable properties (perhaps by combining MCMC schemes or by abandoning one MCMC algorithm in favor of another).

8. The Wishart distribution can be simulated by the Bartlett decomposition: If \( W \sim \mathcal{W}_p(\nu, G) \), then \( W = \mathbf{T} \mathbf{T}' \), where \( \mathbf{T} \) is a lower triangular matrix with \( t_{ij} \sim \chi^2_{\nu-1+i} \) and \( t_{ij} \sim \mathcal{N}(0,1) \), and \( L \) is obtained from the Choleski factorization \( LL' = G \).

9. To simulate from \( \mathcal{T}[\nu, b](\mu, \sigma^2) \), we first simulate a uniform random variate \( U \) and then obtain the required draw as \( \mu + \sigma \Phi^{-1}(p_1 + U(p_2 - p_1)), \) where \( \Phi^{-1} \) is the inverse c.d.f. of the normal distribution, \( p_1 = \Phi((a - \mu)/\sigma) \) and \( p_2 = \Phi((b - \mu)/\sigma) \). Alternatively, the method of Geweke (1991) can be used to sample this distribution.

10. In the analysis of the AR(\(p\)) model conditioned on \( Y_p \), Chib (1993a) showed that all full conditional distributions take standard forms.
